1. Introduction

Since the dawn of time, people have tried to explain their surroundings. Life is all around us in many forms, and as such people have tried to categorize it by keen observation, both through its visual and genetic features. Today, it is organised into a taxonomic hierarchy of eight major taxonomic ranks. The number of known species on Earth is in the millions and climbing every year. Great numbers of species make it difficult to classify species based on images and requires domain knowledge. Therefore, an algorithm with the capability to classify species on the field or from an image using only the image itself could provide great benefits for field researches.

Machine learning allows computers the ability to learn without being explicitly programmed (Samuel). It, together with an increase in available quality data (ImageNet, CIFAR -> dodati reference) has yielded great results in the area of deep learning - a class of machine learning algorithms. Deep learning algorithm's accuracy scales with the amount of data used by the algorithm (referenca), that together with the improvements in hardware - mainly general purpose graphic units (GPUs) - has yielded significant performance gains in the last couple of years. One of the most rapidly advancing field of deep learning is image recognition (VGG16, Inception, Resnet -> reference) with new neural network architectures being developed almost at a yearly basis, the performance of deep neural networks on image recognition has achieved results previously thought impossible.

In this thesis I propose a solution for a scalable classification of species from images, based on convolution neural networks and recent modern deep learning techniques.

2. Research context

To fully understand the depth of the image recognition using deep learning, we need a better understand of the underlying algorithms and methods in machine learning, as well as fundamental terms and concepts. In the next section, an introduction of basic terms is given, followed by a detailed explanation of fundamental machine learning algorithms.

2.1. Definitions and notation

2.1.1. Image representation

Matrix is a rectangular array of numbers. It is used because some numbers are naturally represented as matrices. Matrix A with m rows and n columns often written as $m \times n$ has $m * n$ elements and is denoted as $A_{m,n}$. Elements are denoted as $a_{i,j}$ where i and j correspond to row and column number respectively, as shown in 2.1.

$$A_{m,n} = \begin{bmatrix} a_{1,1} & a_{1,2} & \cdots & a_{1,n} \\ a_{2,1} & a_{2,2} & \cdots & a_{2,n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{m,1} & a_{m,2} & \cdots & a_{m,n} \end{bmatrix} \quad (2.1)$$

Each image is represented as a 3 dimensional matrix. One pixel in the image represent a single element in the matrix and as images have multiple channels (RGB) each channel is a 2 dimensional matrix. Image I denoted as $I_{k,m,n}$ where $k \in [0, 2]$ represent the channel - red, green or blue - and $m, n \in [0, 255]$ represent the pixels in a particular channel as 2 dimensional matrices. Figure 2.1 shows a representation of an image as a 3 dimensional matrix where each pixel is denote as $I_{k,m,n}$.

Figure 2.1: RGB image with 4 pixels represented as a 3 dimensional matrix

2.1.2. Gradient

A gradient is a generalization of the derivative in multi-variable space and as such it is represented as a vector. Like the derivative, it represents the slope of the tangent of the graph of the function. Therefore, it points in the direction of the greatest rate of increase of the function. Gradients are widely used in optimization theory as they allow the parameters to shift in a direction which will minimize or maximize a given function. In machine learning the function we want to minimize will be the loss function, which we will define in further chapters in more detail. Gradient of f is denoted as ∇f , where every component of ∇f is a partial derivative of f , denoted as $\frac{\partial f}{\partial x} \mathbf{e}$. Notice that gradient components are vectors denoted as \mathbf{e} . Every vector is written as a bolded letter. The gradient for a n dimensional space is defined in 2.2.

$$\nabla f = \frac{\partial f}{\partial x_1} \mathbf{e}_1 + \dots + \frac{\partial f}{\partial x_n} \mathbf{e}_n \quad (2.2)$$

2.1.3. Activation functions

Machine learning models use nonlinear functions to gain more capacity - expressiveness. The most popular nonlinear functions are *sigmoid*, *tanh*, *relu*. All nonlinear functions have to have easy to compute gradients, as they are computed on parameters in order to reduce loss as explained above.

$$\text{sigmoid}(x) = \frac{1}{1 + e^{-x}} \quad (2.3)$$

$$\text{tanh}(x) = \frac{1 - e^{-2x}}{1 + e^{-2x}} \quad (2.4)$$

$$\text{relu}(x) = \max(0, x) \quad (2.5)$$

The order of nonlinear functions is given in order of their discoveries. Today relu is used the most, since it solves the problem of vanishing gradients for very deep neural networks, this does not apply to all network types. Recurrent neural networks (RNN)

Figure 2.2: Nonlinear activation functions

are a class of neural networks that often use *tanh* as it is better suited for the particular recurrent architecture.

2.1.4. Metrics

In order to compare different models a set of metrics is employed. Accuracy which gives the accuracy of a model, it is often used on balance datasets (2.6). The problem with unbalanced datasets can be easily explained with a short example. Image having 2 classes $K = \{dog, cat\}$ and there are a total of 100 images in the dataset, of which only 2 are dogs. The model if optimized for accuracy might say the whole dataset is cats which will yield an accuracy of 98%. To solve the previous problem, more metrics were introduced for the task of classification; precision (2.7), recall (2.8) and F1 score (2.9). Precision - positive predictive value - is defined as a fraction of retrieved instances that are relevant. Recall - sensitivity - is a fraction of relevant instances that are retrieved. In order to represent the performance of a model as a single variable F1 score was introduced, it represents a harmonic mean of accuracy and precision.

$$Accuracy = \frac{tp + tn}{tp + tn + fp + fn} \quad (2.6)$$

$$Precision = \frac{tp}{tp + fp} \quad (2.7)$$

$$Recall = \frac{tp}{tp + fn} \quad (2.8)$$

$$F1score = 2 * \frac{precision * recall}{precision + recall} \quad (2.9)$$

Classification results are often represented as a confusion matrix, also known as an error matrix. It is a performance visualisation of a classification model - classifier. To

Table 2.1: Confusion matrix

	prediciton positive	prediction negative
actual positive	True Positive (TP)	False Positive (FP)
actual negative	False Negative (FN)	True Negative (TN)

build the classification matrix, conditions of the experiment must be labeled as positive and negative. Using the cats and dogs example from before and marking the cats and a positive and dogs as a negative class. Doing so creates a 2×2 matrix of actual and predicted values as shown in table 2.1.

2.2. Machine learning

What is,...

Classification, regression,

2.2.1. Supervised and unsupervised learning

Supervised vs unsupervised.
